

A COMPOSITIONAL MODEL TO ASSESS EXPRESSION CHANGES FROM SINGLE-CELL RNA-SEQ DATA

XIUYU MA, AND CHRISTINA KENDZIORSKI, AND MICHAEL A. NEWTON

1. INTRODUCTION

The ability to measure genome-wide gene expression at single-cell resolution has accelerated the pace of biological discovery[?]. Overcoming data analysis challenges caused by the scale and unique variation properties of single-cell data will surely fuel further advances in immunology[?], developmental biology[?], cancer[?], and other areas. Computational tools and statistical methodologies created for data of lower-resolution (e.g. bulk RNA-seq) or lower dimension (e.g. flow cytometry) guide our response to the data science demands of new measurement platforms, but they are not adequate for efficient knowledge discovery in this rapidly advancing domain[?].

An important feature of single-cell studies that could be leveraged better statistically is the fact that cells populate distinct, identifiable subtypes determined by lineage history, epigenetic state, the activity of various transcriptional programs, or other distinguishing factors. Lots of efforts have been made to clustering cells into different cell subtypes, SC3[?], CIDR[?] and ZIFA[?]. Whether or not a determination of cellular subtypes and their frequencies is a task of interest in a given application, we hypothesize that such subtype information may be injected into other inferences in order to improve their operating characteristics. *cumbersome sentence*

Assessing the magnitude and statistical significance of changes in gene expression associated with different cellular conditions has been a central statistical problem in genomics for which new tools specific to the single-cell RNAseq data structure have been deployed: MAST[?], DESEQ2[?], SCDD[?], etc. These tools respond to scRNAseq characteristics, such as high prevalence of zero counts and gene-level multimodality, but none takes explicit advantage of cellular subtype information. We present a simple procedure and supporting theoretical analyses for this purpose. A notable technical innovation is a new prior distribution over pairs of multinomial probability vectors that conveys both marginal Dirichlet conjugacy as well as dependence induced through sharp equalities on aggregated subtype probabilities, which turns out to be key in formulating the posterior probability of changes in expression distributions between conditions.

DEPARTMENT OF BIostatISTICS AND MEDICAL INFORMATICS, UW MADISON,
TECHNICAL REPORT TR***-V1, JULY **, 2018.

Using the proposed compositional model, subtypes inferred from whole genome data improve the analysis of gene-level expression. We utilize the mixture of subtypes to characterize transcripts profile and identify differential distributed genes across conditions in an scRNA-seq experiment. Simulation study suggests that the method provides improved power and precision for identifying differentially distributed genes. Performance on empirical data has been investigated through ten previously published experimental data from conquer[?]. We also obtained asymptotic properties of posterior inference.

The proposed scDDboost methodology extends scDD[?], which similarly treats expression data within a condition as a statistical mixture. The extension provided by the present work is to recognize that this mixture is a mixture over cell subtypes. Thus genome-wide data provide information on mixing proportions, thereby providing useful structural information into each gene-level calculation

2. MODELING

2.1. Data structure, sampling model, and parameters. In modeling scRNASeq data, we imagine that each cell c falls into one of $K > 1$ classes, which we think of as subtypes or subpopulations of cells. For notation, $z_c = k$ means that cell c happens to be of subtype k , with the vector $z = (z_c)$ recording the states of all sampled cells. Knowledge of this class structure prior to measurement is not required, as it will be inferred as necessary from available genomic data. We expect that cells arise from multiple experimental conditions, such as by treatment-control status or some other factors measured at the cell level, but we present our development for the special case of two conditions. Notationally, $y = (y_c)$ records the experimental condition, say $y_c = 1$ or $y_c = 2$ initially: extensions to multiple conditions are discussed in section 6. Let's say condition j measures $n_j = \sum_c 1[y_c = j]$ cells, and in total we have $n = n_1 + n_2$ cells in the analysis. Further let $t_k^j = \sum_c 1[y_c = j, z_c = k]$ denote the number of cells of subtype k in condition j ; we infer something about these counts using genome-wide data. As for molecular data, the normalized expression of gene g in cell c , say $X_{g,c}$, is one entry in a typically large GENES by CELLS data matrix X . Thus, the data structure entails an expression matrix X , a treatment label vector y , and a vector z of latent subtype labels.

We treat subtype counts in the two conditions, $t^1 = (t_1^1, t_2^1, \dots, t_K^1)$ and $t^2 = (t_1^2, t_2^2, \dots, t_K^2)$, as independent multinomial vectors, reflecting the common, two-condition experimental design. Explicitly,

$$t^1 \sim \text{Multinomial}_K(n_1, \phi) \quad \text{and} \quad t^2 \sim \text{Multinomial}_K(n_2, \psi)$$

for probability vectors $\phi = (\phi_1, \phi_2, \dots, \phi_K)$ and $\psi = (\psi_1, \psi_2, \dots, \psi_K)$ that characterize the populations of cells from which the n observed cells are sampled. Our working hypothesis, referred to as the *compositional model*, is that any differences in the distribution of expression $X_{g,c}$ between $y_c = 1$ and $y_c = 2$ (i.e., any condition effects) are attributable to differences between the conditions in the underlying composition of cell types; i.e., owing to

$\phi \neq \psi$. We reckon that cells of any given subtype k will present data according to a distribution reflecting technical and biological variation specific to that class of cells, regardless of the condition the cell finds itself in. Some care is needed in this, as an overly broad cell subtype (e.g. *epithelial cells*) could have further subtypes that show differential response to some treatment, for example, and so cellular condition (treatment) would then affect the distribution of expression data within the subtype, which is contrary to our working hypothesis. Were that the case, we could have refined the subtype definition to allow a greater number of population classes K in order to mitigate the problem of within-subtype heterogeneity. A risk in this approach is that K could approach n , as if every cell were its own subtype. We find, however, that data sets often encountered do not display this theoretical phenomenon when considering a broad class of within-subtype expression distributions. We revisit the issue in discussion section, but for now proceed assuming that cellular condition affects the composition of subtypes but not the distribution of expression within a subtype.

Within the compositional model, let $f_{g,k}$ denote the sampling distribution of expression measurement $X_{g,c}$ assuming that cell c is from subtype k . Then for the two cellular conditions, and at some expression level x , the marginal distributions over subtypes are finite mixtures:

$$f_g^1(x) = \sum_{k=1}^K \phi_k f_{g,k}(x) \quad \text{and} \quad f_g^2(x) = \sum_{k=1}^K \psi_k f_{g,k}(x).$$

We say that gene g is *differentially distributed*, denote DD_g and indicated $f_g^1 \neq f_g^2$, if $f_g^1(x) \neq f_g^2(x)$ for some x , and otherwise it is equivalently distributed (ED_g). Motivated by findings from bulk RNAseq data analysis, we further set each $f_{g,k}$ to have a Negative Binomial form, say with mean $\mu_{g,k}$ and shape parameter α_g ($[\cdot]; [\cdot]; [\cdot]$). This choice proves to be effective in our numerical experiments though it is not critical to the modeling formulation. **maybe a sentence citing previous papers that use finite mixtures per gene; our angle is to extend by allowing genome-wide data to inform mixing proportions**

We seek a useful methodology to prioritize genes for evidence of DD_g . Interestingly, even if we have evidence for condition effects on the subtype frequencies, it does not follow that a given gene will have $f_g^1 \neq f_g^2$; that depends on whether or not the subtypes show the right pattern of *differential expression* at g , to use the standard terminology from bulk RNAseq. For example, if two subtypes have different frequencies between the two conditions ($\phi_1 \neq \psi_1$ and $\phi_2 \neq \psi_2$) but the same aggregate frequency ($\phi_1 + \phi_2 = \psi_1 + \psi_2$), and also if $\mu_{g,1} = \mu_{g,2}$ then, other things being equal, $f_g^1 = f_g^2$ even though $\phi \neq \psi$. Simply, a gene that does not distinguish two subtypes will also not distinguish the cellular conditions if those subtypes appear in the same aggregate frequency in the two conditions, regardless of changes in the individual subtype frequencies. We formalize this idea in order that our methodology has the necessary functionality. To do so, first consider the parameter space $\Theta = \{(\phi, \psi, \mu, \sigma)\}$, where $\phi = (\phi_1, \phi_2, \dots, \phi_K)$ and $\psi = (\psi_1, \psi_2, \dots, \psi_K)$ are as before, where $\mu = \{\mu_{g,k}\}$ holds all the subtype-and-gene-specific expected values, and where $\sigma = \{\sigma_g\}$ holds all the

gene-specific Negative binomial shape parameters. Critical to our construction are special subsets of Θ corresponding to partitions of the K cell subtypes. A single partition, say π , is a set of mutually exclusive and exhaustive blocks, b , say, each a subset of $\{1, 2, \dots, K\}$, and we write $\pi = \{b\}$. Of course, the set Π containing all partitions π of $\{1, 2, \dots, K\}$ has cardinality that grows rapidly with K . We carry along an example involving $K = 7$ cell types, and one three-block partition taken from the set of 877 possible partitions of $\{1, 2, \dots, 7\}$ (Figure 1).

FIGURE 1. Proportions of $K = 7$ cellular subtypes in different conditions. Aggregated proportions of subtype 1 and 2, subtype 3, 4, 5, and subtype 6,7 remained same across conditions while proportion of individual subtype changed. A gene, for example, that shows no differential expression between subtypes 1 and 2, and also none among types 3,4, and 5, and none between 6 and 7 has the same marginal distribution between the two conditions.

For any partition $\pi = \{b\}$, consider aggregate subtype frequencies

$$\Phi_b = \sum_{k \in b} \phi_k \quad \text{and} \quad \Psi_b = \sum_{k \in b} \psi_k,$$

and extend the notation, allowing vectors $\Phi_\pi = \{\Phi_b : b \in \pi\}$ and similarly for Ψ_π . Recall the partial ordering of partitions based on refinement, and note that as long as π is not the most refined partition (every cell type its own block), then the mapping from (ϕ, ψ) to (Φ_π, Ψ_π) is many-to-one. Further, define sets

$$A_\pi = \{\theta \in \Theta : \Phi_b = \Psi_b \forall b \in \pi\}.$$

and

$$M_{g,\pi} = \{\theta \in \Theta : \mu_{g,k} = \mu_{g,k'} \iff k, k' \in b, b \in \pi\}.$$

Under A_π there are constraints on cell subtype frequencies; under $M_{g,\pi}$ there is equivalence in the gene-level distribution of expression between certain subtypes. These sets are precisely the structures needed to address differential distribution DD_g (and its complement, equivalent distribution, ED_g) at a given gene g , since:

Theorem 1. Let $C_{g,\pi} = A_\pi \cap M_{g,\pi}$. For distinct partitions π_1, π_2 , $C_{g,\pi_1} \cap C_{g,\pi_2} = \emptyset$. Further, at any gene g , equivalent distribution is

$$\text{ED}_g = \bigcup_{\pi \in \Pi} C_{g,\pi}.$$

Under the simplifying prior assumption that A_π and $M_{g,\pi}$ are independent, we have directly from Theorem 1 that:

$$(1) \quad 1 - P(\text{DD}_g|X, y) = P(\text{ED}_g|X, y) = \sum_{\pi \in \Pi} P(A_\pi|X, y) P(M_{g,\pi}|X).$$

Thus, the partition representation guides an empirical Bayesian method for scoring differential distribution. In what follows, we develop the modeling and computational elements necessary to efficiently evaluate $P(\text{DD}_g|X, y)$. In overview, the methodological idea is that genome-wide data globally inform the cell subtypes via A_π , and then gene-level data locally drive the posterior of $M_{g,\pi}$. The model provides a specific form of information sharing between genes that leverages the compositional structure of single-cell data.

2.2. Method structure and clustering. ^{**still has no details on clustering methods**}

Our approach take transcripts processed by normalizing methods (e.g. SCnorm [?]). The workflow contains two parts, classify cells into subtypes and posterior inference on distributional change. In the first part, recall subtype is a group of cells with distributions of transcripts that are specific to this group, regardless which condition the cells is from. Thus classification process is blind to conditions and can be done by clustering upon similarities between cells(supplementary material).

Algorithm 1 scDDBoost-core

Input:

GENES by CELLS expression data matrix $X = (X_{g,c})$
cell condition labels $y = (y_c)$
cell subtype labels (estimated) \hat{z}

Output: posterior probabilities of differential distribution from estimated subtypes

- 1: **procedure** SCDDBOOST-CORE(X, y, \hat{z})
 - 2: number of cell subtypes $K = \text{length}(\text{unique}(\hat{z}))$
 - 3: subtype differential expression: $\forall g, \pi$ compute $P(M_{g,\pi}|X, \hat{z})$ using EBSeq[?]
 - 4: cell frequency changes: $\forall \pi$ compute $P(A_\pi|y, \hat{z})$ using Double Dirichlet model
 - 5: posterior probability: $\forall g, P(\text{ED}_g|X, y, \hat{z}) \leftarrow \sum_{\pi} P(M_{g,\pi}|X, \hat{z}) P(A_\pi|y, \hat{z})$
 - 6: **return** $\forall g, P(\text{DD}_g|X, y, \hat{z}) = 1 - P(\text{ED}_g|X, y, \hat{z})$
-

After identification of subtypes, the second part of our procedure infers patterns of differential expression($M_{g,\pi}$) and aggregated proportions of subtypes(A_π) through empirical Bayes. Specifically, $P(M_{g,\pi}|X, \hat{z})$ is done with EBSeq[?] and we present details of calculating

$P(A_\pi|\hat{z})$ in next section. Combining those components, per gene differential distributed probability is obtained.

One advantage of our approach is that the posterior inference can be incorporate with different clustering methods. With the development of technology, clustering methods taking care of newly discovered characteristic of scRNA seq data (e.g. SC3[?], CIDR[?] and ZIFA[?]) could be substituted with our default one. No matter what clustering method is used, we estimate the mixture structure utilizing the whole genome information rather than estimating a gene specific mixture structure solely using information of that gene. Due to this reason, our model is more capable of capturing characteristic of scRNA seq data than scDD and we name our approach SCDDBOOST.

Although there are various options for clustering methods, none of them guarantee the accuracy and posterior inference can be sensitive to the initial partition. Here we provide a method to make our inferences robust to partitions. Given number of subtypes K , the final posterior probabilities is obtained by averaging results from iterative run of SCDDBOOST-CORE with randomly generated subtype labels z^* . Taking account of information contained in $D = \text{dist}(X)$, instead of purely random assigning subtype labels, we generate the distance matrices of cells D^* by adding noises to the original one and assign labels based on D^* . Specifically, we random sample a noise vector e with length equal to number of cells and components are i.i.d. exponentially distributed. We obtain D^* by adding noises: $D^* = D + e\mathbf{1}^T + \mathbf{1}e^T$. For D^* we still have triangle inequality held as $d_{i,j}^* + d_{j,k}^* \geq d_{i,k}^*$, it is still a valid distance matrix. After robustification, we select number of clusters K that posterior probabilities do not vary too much under K and $K + 1$. We validate our procedure in simulated and empirical data

Algorithm 2

Input:

GENES by CELLS expression data matrix $X = (X_{g,c})$
 cell condition labels $y = (y_c)$
 number of cell subtypes K
 number of randomized clusterings n_r
 regularization parameter λ

Output: posterior probabilities of differential distribution

procedure SCDDBOOST(X, y, K, n_r, λ)

- 2: distance matrix: $D = \text{dist}(X) \leftarrow$ pairwise distances between cells (columns of X)
 - repeat**
 - 4: Exponential noise vector: e , with components $\sim \text{Exp}(\lambda)$
 randomized distance matrix: $D^* \leftarrow D + e\mathbf{1}^T + \mathbf{1}e^T$
 - 6: $P^* \leftarrow \text{SCDDBOOST-CORE}(X, y, D^*, K)$
 - until** n_r randomized distance matrices
 - 8: **return** $\forall \text{genes } g, P(\text{DD}_g|X, y) = \frac{1}{n_r} \sum_{D^*} P_g^*$
-

In general, we observed that averaged adjusted rand index as well as rand index of mode of partitions based on randomized distance matrices is higher (better estimation) than that of partition based on original distance matrix (supplementary material). We view algorithm scDDboost1 as an advanced version of scDDboost0 as it gives improved result depends on finer estimated partition of cells. All the results of scDDboost from simulation and empirical studies are obtained via scDDboost1.

3. EMPIRICAL BAYES

3.1. Double Dirichlet model. **** ON THE PRIOR INDEPENDENCE**** This expresses the idea that subtype proportions (ϕ, ψ) are uninformative about the mean expression levels $\{\mu_{g,i}\}$. Under this assumption: ******

Here we describe a prior $p(\phi, \psi)$ that is conjugate to multinomial sampling but that also enables downstream gene-specific inferences about differential distribution when certain cell types do not differ in their expression distributions.

For our purposes, the prior will have a spike-slab structure that mixes over distinct patterns of equality of π -associated accumulated probabilities:

$$p(\phi, \psi) = \sum_{\pi \in \Pi} P(A_\pi) p(\phi, \psi | A_\pi)$$

Upon setting up a prior $p(\phi, \psi)$ that can mix over structures A_π , we can obtain posterior inference $P(A_\pi | t^1, t^2)$

Initially, the multitude of $P(A_\pi)$'s will be preset constants. To complete the prior specification $p(\phi, \psi)$, consider further scalars $\alpha_k > 0$ for each class k and $\beta_b > 0$ for each potential block b . (Extending the notational convention, α_b is the vector of α_k for $k \in b$, and β_π is the vector of β_b for $b \in \pi$.) For any block b consider conditional probabilities

$$\tilde{\phi}_b = \frac{\phi_b}{\Phi_b} \quad \tilde{\psi}_b = \frac{\psi_b}{\Psi_b}$$

which indicate the conditional probability of each class k given that the cell is of one of the types in b . Assume that conditional upon A_π ,

$$\Phi_\pi \sim \text{Dirichlet}_{N(\pi)}[\beta_\pi]$$

where $N(\pi)$ is the number of blocks b in π , and further that accumulated probabilities are the same between the two source conditions: $\Phi_\pi = \Psi_\pi$. Finally, assume that for each $b \in \pi$,

$$\tilde{\phi}_b, \tilde{\psi}_b \sim_{\text{i.i.d.}} \text{Dirichlet}_{N(b)}[\alpha_b]$$

where $N(b)$ is the number of cell types in block b . In other words, if A_π is the active structure, then accumulated probability vectors Φ_π and Ψ_π are equal between the two

source conditions, though the sub-block class-specific rates ϕ_k and ψ_k may differ, as would (re-normalized) independent Dirichlet-distributed vectors. Taken together,

$$p(\phi, \psi | A_\pi) = p(\Phi_\pi, \Psi_\pi | A_\pi) \prod_{b \in \pi} [p(\tilde{\phi}_b) p(\tilde{\psi}_b)]$$

with

$$p(\Phi_\pi, \Psi_\pi | A_\pi) = \frac{\Gamma(\sum_{b \in \pi} \beta_b)}{\prod_{b \in \pi} \Gamma(\beta_b)} \left[\prod_{b \in \pi} \Phi_b^{\beta_b - 1} \right] 1[\Phi_\pi = \Psi_\pi]$$

and

$$p(\tilde{\phi}_b) = \frac{\Gamma(\sum_{k \in b} \alpha_k)}{\prod_{k \in b} \Gamma(\alpha_k)} \prod_{k \in b} \tilde{\phi}_k^{\alpha_k - 1}, \quad p(\tilde{\psi}_b) = \frac{\Gamma(\sum_{k \in b} \alpha_k)}{\prod_{k \in b} \Gamma(\alpha_k)} \prod_{k \in b} \tilde{\psi}_k^{\alpha_k - 1}.$$

3.2. Predictive probabilities: For notation, we use ϕ_b for the vector of values ϕ_k for $k \in b$, and similarly for ψ_b . Analogously, Φ_π and Ψ_π are vectors of accumulated class probabilities ϕ_b and ψ_b for all $b \in \pi$, respectively.

In order to get the posterior probability $p(A_\pi | t^1, t^2)$, we need to calculate

$$\begin{aligned} p(A_\pi | t^1, t^2) &\propto p(A_\pi, t^1, t^2) = \int_{A_\pi} p(t^1, t^2 | \phi, \psi) p(\phi, \psi) d\phi d\psi \\ &= \sum_{\pi' \in \Pi} \int_{A_\pi} p(t^1, t^2 | \phi, \psi) p(\phi, \psi | A_{\pi'}) p(A_{\pi'}) d\phi d\psi \end{aligned}$$

For simplicity of notation, let $w(\pi_1, \pi_2) = \int_{A_{\pi_1}} p(t^1, t^2 | \phi, \psi) p(\phi, \psi | A_{\pi_2}) p(A_{\pi_2}) d\phi d\psi$, then $p(A_\pi | t^1, t^2) \propto \sum_{\pi' \in \Pi} w(\pi, \pi')$. To calculate component $w(\pi, \pi')$, recall refinement and coarseness relationship between partitions, we say a partition $\tilde{\pi}$ is a refinement of another partition π if $\forall b \in \pi$ there exists $s \subset \tilde{\pi}$ such that $\bigcup_{b' \in s} b' = b$. We say π is a coarseness of $\tilde{\pi}$ when $\tilde{\pi}$ refines π . we have following theorem

Theorem 2. *If π' is a refinement of π then $w(\pi, \pi') = w(\pi', \pi')$ otherwise $w(\pi, \pi') = 0$*

Consequently, let $RF(\pi)$ be the collection of finer partition of π , we have the posterior probability:

$$p(A_\pi | t^1, t^2) \propto \sum_{\pi' \in RF(\pi)} w(\pi', \pi')$$

Using the Dirichlet-Multinomial conjugacy and the collapsing property of these distributions ([?]), we get closed formulas for the predictive probability of cell-type counts t^1 and t^2 . Fixing π , let $t_b^j = \sum_{k \in b} t_k^j$, for cell conditions $j = 1, 2$, record the total numbers of cells

accumulated over all types in block b . And following our notation convention, t_π^j is the vector of these counts over $b \in \pi$. From the prior and model structure

$$w(\pi, \pi) = p(t^1|t_\pi^1) p(t^2|t_\pi^2) p(t_\pi^1, t_\pi^2|A_\pi) p(A_\pi).$$

Conditional independence of t^1 and t^2 given the block-level totals t_π^1 and t_π^2 on A_π reflects the possible differential class proportion structure within blocks but between cell conditions. For either cellular group $j = 1, 2$, we find, after some simplification, the following Dirichlet-Multinomial masses:

$$(2) \quad p(t^j|t_\pi^j) = \prod_{b \in \pi} \left\{ \left[\frac{\Gamma(t_b^j + 1)}{\prod_{k \in b} \Gamma(t_k^j + 1)} \right] \left[\frac{\Gamma(\sum_{k \in b} \alpha_k)}{\prod_{k \in b} \Gamma(\alpha_k)} \right] \left[\frac{\prod_{k \in b} \Gamma(\alpha_k + t_k^j)}{\Gamma(t_b^j + \sum_{k \in b} \alpha_k)} \right] \right\}$$

and

$$(3) \quad p(t_\pi^1, t_\pi^2|A_\pi) = \left[\frac{\Gamma(n_1 + 1)\Gamma(n_2 + 1)}{\prod_{b \in \pi} \Gamma(t_b^1 + 1)\Gamma(t_b^2 + 1)} \right] \left[\frac{\Gamma(\sum_{b \in \pi} \beta_b)}{\prod_{b \in \pi} \Gamma(\beta_b)} \right] \left[\frac{\prod_{b \in \pi} \Gamma(\beta_b + t_b^1 + t_b^2)}{\Gamma(n_1 + n_2 + \sum_{b \in \pi} \beta_b)} \right].$$

Let's look at some special cases to dissect this result.

Case 1. If π has a single block equal to the entire set of cell types $\{1, 2, \dots, K\}$, then $t_b^j = n_j$ for both $j = 1, 2$, and the second formula reduces, correctly, to $p(t_\pi^1, t_\pi^2|A_\pi) = 1$. Further,

$$p(t^j|t_\pi^j) = \left[\frac{\Gamma(n_j + 1)}{\Gamma(n_1 + \sum_{k=1}^K \alpha_k)} \right] \left[\frac{\Gamma(\sum_{k=1}^K \alpha_k)}{\prod_{k=1}^K \Gamma(\alpha_k)} \right] \left[\prod_{k=1}^K \frac{\Gamma(\alpha_k + t_k^j)}{\Gamma(t_k^j + 1)} \right]$$

which is the well-known Dirichlet-multinomial predictive distribution for counts t^j [?]. E.g, taking $\alpha_k = 1$ for all types k we get the uniform distribution

$$p(t^j|t_\pi^j) = \frac{\Gamma(n_j + 1)\Gamma(K)}{\Gamma(n_j + K)}.$$

Case 2. At the opposite extreme, π has one block b for each class k . Then $t_b^j = z_k^j$, and $p(t^j|t_\pi^j) = 1$, and further, assuming $\beta_b = \alpha_k$,

$$p(t_\pi^1, t_\pi^2|A_\pi) = \left[\frac{\Gamma(n_1 + 1)\Gamma(n_2 + 1)}{\prod_{k=1}^K \Gamma(t_k^1 + 1)\Gamma(t_k^2 + 1)} \right] \left[\frac{\Gamma(\sum_{k=1}^K \alpha_k)}{\prod_{k=1}^K \Gamma(\alpha_k)} \right] \left[\frac{\prod_{k=1}^K \Gamma(\alpha_k + t_k^1 + t_k^2)}{\Gamma(n_1 + n_2 + \alpha_k)} \right].$$

which corresponds to Dirichlet-multinomial predictive distribution for counts $t^1 + t^2$ since t^1 and t^2 are identical distributed in this case.

Regardless of the partition, log scale probabilities are readily evaluated given hyper-parameters $\{\alpha_k\}$ and $\{\beta_b\}$ and for cell-type counts t^1 and t^2 .

For asymptotic properties of the posterior probabilities, we demonstrated them in section 6.

4. OPERATING CHARACTERISTICS

4.1. Splatter Simulation. A simulation study was conducted to assess the performance of scDDboost in identifying DD genes. We simulate data by splatter[?] with approximate 200 cells each condition and 7 subtypes with proportions ϕ and ψ from Fig 1 satisfying constraints: $\phi_1 + \phi_2 = \psi_1 + \psi_2$, $\phi_3 + \phi_4 + \phi_5 = \psi_3 + \psi_4 + \psi_5$ and $\phi_6 + \phi_7 = \psi_6 + \psi_7$. Each subtype has 10% genes to be differential expressed. We view the differences among subtypes by projecting transcripts profiles of cells into its first two principal components(Fig 2). We observed subtypes are well separated, which is driven by genes with heterogeneous distribution between subtypes.

FIGURE 2. first two principal components of transcripts, which demonstrates the difference between subtypes. Even if we projected transcripts of cells into two dimensional space, we observe subtypes are well separated.

We determine the number of subtypes by searching a range of candidates(from 1 to 9 based on our empirical experience). Given number of subtypes, we obtain a subtype structure of cells, which will further be fed into computing the posterior probabilities. We visualize the change between posterior probabilities under number of clusters i and $i+1$ (i from 1 to 8). It typically remains stable when number of cluster is above a number that is smaller than 9 (Fig 3) In the simulated data, the posterior probability become stable when we overestimate the number of subtypes. We found the true number of subtypes is 7 and correctly identify the subtypes of cells.

10% DE genes in each subtype results in total 8704 DD genes and 8669 ED genes in the mixture of the 7 subtypes. Table 1 are numbers of DD or DE genes identified by four methods (scDDboost, scDD, MAST and DESeq2) with target FDR at 5 %.

scDDboost identified most true DD genes, the reason is that mean expression shifts between conditions is not as significant as mean expression shifts between subtypes, which limits

	scDDboost	scDD	MAST	DESeq2
DD or DE genes	5126	1593	2559	3000
True positive	5094	1570	2508	2928
false positive	32	23	51	72

TABLE 1. number of true positive and false positive genes identified by four methods. Target FDR at 5%

the power of MAST and DESeq2. Our approach and scDD considered mixture structure underlying the transcripts but scDD did not use the whole genome information to infer mixture components, which leads to inaccurate clustering at gene level and reduce the power. Under randomized distance, scDDboost gave an accurate estimation of subtypes and thus are more sensitive to the mean expression change among subtypes. We also compare roc curves of scDDboost, scDD, MAST and DESeq2. (Fig 4)

FIGURE 3. comparison of posterior probabilities of being DD among different number of subtypes, when we underestimate the number of subtypes, the difference is huge, see PDD between 6 subtypes and 7 subtypes. There is an approximate horizontal line with massive points at the top of left panel, which indicate that we underestimate lots of DD genes due to underestimate the number of subtypes. While in the case when we overestimate the number of subtypes 7 subtypes vs. 8 subtypes, though inflating PDD but the variation of difference is small, from 6 to 8 subtypes the PDD become more linear related.

FIGURE 4. Roc curve of scDDboost, scDD, MAST and DESeq2, scDDboost has largest area under the roc curve. Roc curves of other three methods are similar. For those roc curve there is bigger difference at low level of false positive rate, as scDDboost identified twice many true DD genes as other methods.

Since we are modeling gene transcript within each subtype as negative binomial distributed and we only test one parameter(mean) change among subtypes. In some scenario, it could be insufficient to model the variability within subtype. Even though there is no mean expression change among subtypes but more subtle distributional change occurred among subtypes changed, EBSeq would fail to detect the discrepancies between subtypes, thus limit power of scDDboost.

4.2. Empirical study. **Conquer examples...null and alternative**

We use ten datasets from conquer[?] to test performance of our method on empirical data. We compare our results with scDD[?], MAST[?] and DESeq2[?], we have also investigated performance of scDDboost under different clustering method, here sc3[?] is used to couple with scDDboost0, as sc3 did not provide user accessible distance matrix.

Data set	Compared cell subsets	Number of cells/condition	Organism	Ref
GSE45719	16-cell stage blastomere vs Mid blastocyst cell (92-94h post- fertilization)	50, 60	mouse	[?]

TABLE 2. single cell transcripts profiles used for differential expression or distribution method evaluation

We have table of numbers of differentially expressed genes of each dataset by MAST and DESeq2, and numbers of differentially distributed genes of each dataset by scDDboost and scDD.

We found that bulk method DESeq2 tends to have the most number of DE genes. But among single cell methods, scDDboost usually identified the most DD genes. Further we observed quite a few genes uniquely identified by scDDboost are likely to have different distribution across conditions. For example, Fig 5, we use violin plot to demonstrate the log expression profiles among DEC and EC.

Data set	scDDboost	scDDboost-sc3	scDD	MAST	DESeq2	total number of genes
GSE45719	5758	4228	6416	5652	11202	45686

TABLE 3. number of DD genes detected by different methods

FIGURE 5. Densities of log transformed transcripts, 6 DD genes uniquely identified by scDDboost, for data GSE75748, DEC vs. EC, We observe some of the genes are different distributed across conditions.

4.3. Empirical study: null cases. Although bulk methods seems to be the most powerful one, we found it also has a higher false discovery rate comparing to single cell methods. We validate false discovery rate on ten null datasets from table 1. For each null dataset, we randomly split the cells from one condition into two subsets and test difference of gene expression between those subsets. Since the two subsets of cells actually came from same condition, there should not be any differential distributed genes, any positive call would be a false positive. We repeat the random split and testing for five times on each null data set. We evaluate the type I error control for the methods returning nominal p-values, by recording the fraction of genes(with a valid p-value) that are assigned a nominal p-value below 0.05 (Fig 6).

scDDboost could control FDR since we assume cells are sampled from population composed of different subtypes. Cells from one subtype are equal likely to be assigned to either one of the two subsets. Consequently, it is very likely that proportions of subtypes remain unchanged among the two subsets.

Data set	Compared cell subsets	Number of cells/condition	Organism
GSE45719null	16-cell stage blastomere	50	mouse
GSE45719null	16-cell stage blastomere	50	mouse

TABLE 4. datasets used for null cases, as cells are coming from same biological condition, there should not be any differential distributed genes, any positive call is false positive

FIGURE 6. FDR of scDDboost, scDD, MAST and DESeq2 on null dataset from table 1, DESeq2 usually identify a lot but may lose the control of type I error. While other single cell methods could control FDR.

4.4. Number of subtypes. From our empirical experience, it is typical K will not be larger than 8. We demonstrate the change of posterior probabilities of differential distribution given different number of subtypes at data GSE75748 and GSE48968. In both cases, if allowing one more subtype would result in a lot increases in posterior probabilities, which suggests that the number of subtypes is underestimated since we found more distribution differences between conditions given one more mixture component. If posterior inference is stable after increasing the number of subtypes, then we consider previous number of subtypes to be optimal.

FIGURE 7. selecting number of subtypes for data GSE75748, we observe posterior probabilities become stable at more than 6 subtypes. Since increasing number of subtypes tends to decrease sample size of each subtypes, make complicate constraints for equivalent distribution and inflate estimated PDD. We select number of subtypes to be 7

FIGURE 8. selecting number of subtypes for data GSE48968, we observe posterior probabilities become stable at more than 5 subtypes

4.5. Bursting parameters. D3E[?] is a distributional method that can identify bursting parameters of transcripts. Rate of promoter activation, rate of promoter inactivation and the rate of transcription when the promoter is in the active state are estimated by D3E. We investigate DD genes identified by scDDboost and their change of those three parameters on dataset EMTAB2805

FIGURE 9. 2D histogram for bursting parameters of DD genes identified by scDDboost from dataset EMTAB2805 estimated by D3E. Left panel : comparison of rate of promoter activation between two conditions, similarly, middle panel : rate of promoter inactivation and right panel: rate of transcription when the promoter is in the active state. We observe that difference between transcription rate is smaller compare to difference between the activation and inactivation rate.

We observed that DD genes identified by scDDboost tends to have similar transcription rate when the promoter is active across condition, while there are lots of variabilities in the action and inactivation rate. Estimations from D3E reveals that the major factor to drive DD genes are activation and inactivation rate (proportions of different subtypes), it make sense to consider mixture model like scDDboost.

5. THEORETICAL ISSUES

5.1. Posterior consistency. Under some parameters settings, the double dirichlet prior will have limited resolution and lead to inconsistency of posterior probabilities, which we investigate with the following asymptotic analysis.

We first give the expression of posterior probability. Since there is no information favorable of any particular A_π , we select discrete uniform distribution as the prior for it, then the posterior probability is

$$(4) \quad p(A_\pi | t^1, t^2) = c * \sum_{\pi' \text{ refines } \pi} p(t^1 | t_{\pi'}^1) p(t^2 | t_{\pi'}^2) p(t_{\pi'}^1, t_{\pi'}^2 | A_{\pi'})$$

for a normalizing constant $\frac{1}{c} = \sum_{\pi' \in \Pi} p(t^1 | t_{\pi'}^1) p(t^2 | t_{\pi'}^2) p(t_{\pi'}^1, t_{\pi'}^2 | A_{\pi'})$.

Let $\Omega = \{(\phi, \psi) : \sum_{i=1}^K \phi_i = \sum_{i=1}^K \psi_i = 1, \phi_i \geq 0, \psi_i \geq 0, i = 1, \dots, K\}$ be the whole space. There is a subset of Ω we lack posterior inference. Let us first see an example:

In Fig 10, there are four subtypes, the rectangle with magenta boundary is a simplex $A_{\pi_1} = \{(\phi, \psi) : \phi_1 + \phi_2 = \psi_1 + \psi_2\}$, the rectangle with blue boundary is a simplex $A_{\pi_2} = \{(\phi, \psi) : \phi_1 + \phi_3 = \psi_1 + \psi_3\}$. The green line refers to $A_{\pi_3} = \{(\phi, \psi) : \phi_1 = \psi_1, \phi_2 = \psi_2\}$,

FIGURE 10. Four subtypes of cells, simplexes of (ϕ, ψ) satisfying different constraints.

the yellow line refers to $A_{\pi_4} = \{(\phi, \psi) : \phi_1 = \psi_1, \phi_3 = \psi_3\}$, the purple line refers to $A_{\pi_5} = \{(\phi, \psi) : \phi_1 + \phi_2 = \psi_1 + \psi_2, \phi_1 + \phi_3 = \psi_1 + \psi_3\}$, which is the intersection of A_{π_1} and A_{π_2} , and finally the black dot which is the intersection of those three lines refers to the simplex with finest partitions, $\phi_i = \psi_i, \forall i = 1, \dots, 4$. We lack posterior inference for (ϕ, ψ) along the purple line except the black dot. While on the green line, yellow line and black dot, we have consistent posterior inference (theorem 2). To explain why some space lacking posterior inference and define such space, we define a special subset A_π^* of simplex A_π . $A_\pi^* = A_\pi \setminus \bigcup_{\tilde{\pi} \text{ is not coarser than } \pi} A_{\tilde{\pi}}$, A_π^* is obtained by removing all intersection with other $A_{\tilde{\pi}}$ (excluding those $A_{\tilde{\pi}}$ that is superset of A_π) from A_π . Since we removed those intersection parts. It is intuitive that A_π^* will be disjoint subsets of Ω .

Proposition 1. *if $\pi_1 \neq \pi_2$, then $A_{\pi_1}^* \cap A_{\pi_2}^* = \emptyset$*

Let $Q = \Omega \setminus \bigcup_{\pi \in \Pi} A_\pi^*$, and we have following proposition of the existence of Q .

Proposition 2. *Let K be number of subtypes. When $K > 3, Q \neq \emptyset$, when $K \leq 3, Q = \emptyset$*

When the number of subtypes is bigger than three, we lack posterior inference on Q . To see that we can rewrite A_π^* as $A_\pi^* = A_\pi \setminus \bigcup_{\tilde{\pi} \text{ is not coarser than } \pi} (A_{\tilde{\pi}} \cap A_\pi)$, $\tilde{\pi}$ is not coarser than

π , which is equivalently to say π is not refinement of $\tilde{\pi}$. By lemma 1, $A_{\tilde{\pi}} \cap A_{\pi}$ is a lower dimensional subset of A_{π} . So $A_{\pi} \setminus A_{\pi}^*$ is a lower dimensional subset of A_{π} . For posterior on Q , it degenerates to integral on a lower dimensional subset of the simplex associating with densities, which will vanish

Proposition 3. *When $K > 3$, $p(Q|z^1, z^2) = 0$*

But for $(\phi, \psi) \in \Omega \setminus Q$, we have consistent posterior inference. Assuming $\alpha_i = 1, \forall i$ in (2) and $\beta_b = \sum_{i \in b} \alpha_i$ in (3), plug in (4) then we have simplified

$$(5) \quad p(A_{\pi}|t^1, t^2) = \frac{1}{c'} \sum_{\pi' \in \text{RF}(\pi)} \prod_{b \in \pi'} \frac{\Gamma(\beta_b + t_b^1 + t_b^2)}{\Gamma(\beta_b + t_b^1) \Gamma(\beta_b + t_b^2)}$$

$c' = c / \frac{\Gamma(n+1)\Gamma(n+1)\Gamma(K)}{\Gamma(2n+K)}$ And we have theorem 3.

Theorem 3. *Let $n = \min(n_1, n_2)$ be the smaller number of cells of two conditions and $n_1 = O(n_2)$, when parameter $(\phi, \psi) \in \Omega \setminus Q$ we have*

$$p(A_{\pi}|t^1, t^2) \xrightarrow[n \rightarrow \infty]{a.s.} \begin{cases} 1 & \text{if } (\phi, \psi) \in A_{\pi} \\ 0 & \text{otherwise} \end{cases}$$

Things become more complicate when (ϕ, ψ) falling into Q , we know $p(Q|t^1, t^2)$ vanishes, but $p(A_{\pi}|t^1, t^2)$ may not.

Recall $N(\pi)$ represents number of blocks b in π . Let $S = \{\pi, (\phi, \psi) \in A_{\pi}\}$, which is the collection of partitions whose associated simplexes covering (ϕ, ψ) . Let $N^* = \max_{\pi \in S} N(\pi)$, which is the max number of blocks of partitions from S . Let $S^* = \{\pi, (\phi, \psi) \in A_{\pi} \text{ and } N(\pi) = N^*\}$, which is the collection of partitions that covering (ϕ, ψ) with number of blocks equal to the max number N^* .

For example, when $K = 7$, For a $(\phi, \psi) \in A_{\pi_1} \cap A_{\pi_2} \cap A_{\pi_3}$, $\pi_1 = \{\{1, 2, 3\}, \{4, 5, 6, 7\}\}$, $\pi_2 = \{\{1, 6, 7\}, \{2, 4\}, \{3, 5\}\}$, $\pi_3 = \{\{1, 2, 3, 4, 5, 6\}\}$, and also (ϕ, ψ) does not belong to any other simplex A_{π} . Then $S = \{\pi_1, \pi_2, \pi_3\}$, $N^* = 3$, $S^* = \{\pi_2\}$.

Denote components from right hand side of (5): $\frac{1}{c'} \prod_{b \in \pi} \frac{\Gamma(\beta_b + t_b^1 + t_b^2)}{\Gamma(\beta_b + t_b^1) \Gamma(\beta_b + t_b^2)} = J(t^1, t^2, \pi)$. We have theorem 4.

Theorem 4. *Following the setting in theorem 2, when parameter $(\phi, \psi) \in Q$, and we have*

$$J(t^1, t^2, \pi) \xrightarrow[n \rightarrow \infty]{a.s.} \begin{cases} m(\pi) & \pi \in S^* \\ 0 & \text{otherwise} \end{cases}$$

and $\sum_{\pi \in S^*} m(\pi) = 1, m(\pi) > 0$

proofs are in the appendix.

Still using above example, in limiting case, we have $p(A_{\pi_3}|t^1, t^2) = 1$, $p(A_{\pi_2}|t^1, t^2) = 1$ and $p(A_{\pi_1}|t^1, t^2) = 0$. When the DE pattern is B_{π_1} for some genes. Since our underestimation of $p(A_{\pi_1}|z^1, z^2) = 0$, we will falsely classify those genes as differential distributed.

The asymptotic properties help us gain insight of the performance of our approach, scD-Boost may work poorly, when $(\phi, \psi) \in Q$, we may underestimate the posterior probability of true proportion change pattern, which reduce the posterior probabilities of true negative and enlarge false positive rate.

5.2. Random weighting.

6. DISCUSSION AND FUTURE WORK

We have presented scDDboost, a compositional model for the analysis of scRNA-seq data. scDDboost make whole genome information shared at gene level inference and is flexible of integrating with different cell clustering methods. scDDboost accounts for the over-dispersion and multi-modality of single-cell data by modeling expression data as mixture of subtypes. Information from the change of subtypes' proportions and mean expressions is combined to infer distributional changes of gene expression. We developed a prior distribution that can be used to estimate sharp equalities on aggregated subtype probabilities. Using simulation studies, we have demonstrated that our method outperforms existing approaches when there existing multiple cell types.

6.1. Multi-conditions. One direction for future work is to extend the compositional model to multi-conditions case. As scRNA seq data is a time course data, it may be more interested to consider inference of distributional changes across multiple conditions. We outline our procedure in the following.

Assume there are T conditions, K subtypes, Let f_g^c denotes distribution of expression of gene g at condition c . Partition of conditions are π^1, \dots, π^{n_T} with superscripts, and π_1, \dots, π_{n_K} with subscripts refer to partition of subtypes. Then, given a partition of conditions, say π^1 , the corresponding distribution change of a gene g is $D_g^{\pi^c} = \{\forall b \in \pi^c, f_g^i = f_g^j, f_g^i \neq f_g^m \forall i, j \in b, \forall m \notin b\}$. Similar in two conditions case, to express distributional change in terms of parameters change, we consider parameter space

$$\Theta = \{\phi^1, \dots, \phi^T, \mu^1, \dots, \mu^K\}$$

where ϕ^l is proportions of subtypes at condition l and $\mu_k = \{\mu_{g,k}\}$ is gene-specific expected values at subtype k .

Define

$$A_{\pi_k}^{\pi^l} = \{\forall b \in \pi^l, \forall i \in b, \forall m \notin b, \exists b' \in \pi_k, \sum_{s \in b'} \phi_s^i \neq \sum_{s \in b'} \phi_s^m; \forall b' \in \pi_k, \forall i, j \in b. \sum_{s \in b'} \phi_s^i = \sum_{s \in b'} \phi_s^j\}$$

Indeed, $A_{\pi_k}^{\pi^l}$ and M_{g,π_k} are precisely the structures needed to address differential distribution $D_g^{\pi^l}$

Theorem 5. *If $\pi^l \neq \pi^{MF} = \{\{1\}, \dots, \{T\}\}$, the most refined partition. Then*

$$D_g^{\pi^l} = \begin{cases} \bigcup_{\pi_k \neq \pi_0} A_{\pi_k}^{\pi^l} \cap M_{g,\pi_k} & \text{if } \pi^l \neq \pi^0 \\ \bigcup_{\pi_k} A_{\pi_k}^{\pi^l} \cap M_{g,\pi_k} & \text{if } \pi^l = \pi^0 \end{cases}$$

where $\pi_0 = \{1, 2, \dots, K\}$, $\pi^0 = \{1, 2, \dots, T\}$ are the most coarse partitions.

If $\pi^l = \pi^{MF}$, which corresponds to the case that g in each condition has a distinguished distribution. Then

$$D_g^{\pi^l} = \bigcap_{\pi^j \neq \pi^{MF}} [M_{g,\pi_i}^c \bigcup_{\pi_i} (A_{\pi_i}^{\pi^j})^c]$$

Where A^c refers to the complement set of A

We prioritize $A_{\pi_k}^{\pi^l}$ via following procedure:

$$(6) \quad \phi^b = \{\phi^k, k \in b\}$$

$$(7) \quad P(\phi | A_{\pi_k}^{\pi^l}) = \prod_b P(\phi^b | A_{\pi_k}^{\pi^l})$$

$$(8) \quad P(\phi^b | A_{\pi_k}^{\pi^l}) = P(\Phi | A_{\pi_k}^{\pi^l}) P(\tilde{\phi} | A_{\pi_k}^{\pi^l})$$

Where $\Phi = \{\Phi_{b'}, b' \in \pi_k\}$, $\Phi_{b'} = \sum_{i \in b'} \phi_i^j$, $j \in b$, $\Phi_{b'} \sim \text{dirichlet}(\beta)$ and $\tilde{\phi} = \{\tilde{\phi}^j, j \in b\}$, $\tilde{\phi}^j =$

$(\tilde{\phi}_1^j, \dots, \tilde{\phi}_K^j)$, $\tilde{\phi}_i^j = \frac{\phi_i^j}{\Phi_{b'}^j}$, for $i \in b'$

Since there are a lot of overlapping among $A_{\pi_k}^{\pi^l}$, care must be taken to account for competing issue of prior predictive function. Empirical study may give suggestion of modifying the prior.

6.2. Randomized distance. From simulation and empirical studies, we obtained stabilized posterior probabilities by averaging results on random generated distance matrices. It remains unclear how clustering on randomized distance matrices approximate the true partition. We seek a theoretical justification of the benefit from randomized distance.

APPENDIX A

Lemma 1. *If π_2 is not refinement of π_1 then $A_{\pi_1} \cap A_{\pi_2}$ is a lower dimensional subset of A_{π_2}*

Proof of theorem 2

Proof. by lemma 1, it is easy to verify. \square

where $p(t^1, t^2 | \phi, \psi) = p(t^1 | \phi) p(t^1 | \psi)$, $t^1 | \phi \sim \text{multinomial}(n_1, \phi)$, $t^2 | \psi \sim \text{multinomial}(n_2, \psi)$. Recall the definition of $A_\pi = \{(\phi, \psi) : \Phi_b = \Psi_b\}$ and A_π is a simplex. Denote the finest partition as $\pi_F = \{\{1\}, \{2\}, \dots, \{K\}\}$, associated simplex $A_{\pi_F} = \{(\phi, \psi) : \phi_i = \psi_i, i = 1, \dots, K\}$ for any two partition π_1 and π_2 , intersection of their associated simplex must not be empty since $A_{\pi_F} \subset A_{\pi_1} \cap A_{\pi_2} \neq \emptyset$. To discuss the issue of overlapping of simplex A_π , we first introduce some notations. The whole space $\Omega = \{(\phi, \psi), \phi_i, \psi_i > 0 \text{ and } \sum_{i=1}^K \phi_i = \sum_{i=1}^K \psi_i = 1\}$ and we define the refinement and coarseness relationship between partitions, we say a partition $\tilde{\pi}$ refines another partition π if $\forall b \in \pi$ there exists $s \subset \tilde{\pi}$ such that $\cup_{b' \in s} b' = b$. When $\tilde{\pi}$ refines π , we say $\tilde{\pi}$ is a refinement of (finer than) π or π is a coarseness of (coarser than) $\tilde{\pi}$. Observe that if π' refines π , then $A_\pi \cap A_{\pi'} = A_{\pi'}$, $\int_{A_\pi \cap A_{\pi'}} p(z^1, z^2 | \phi, \psi) p(\phi, \psi | A_{\pi'}) d\phi d\psi = \int_{A_{\pi'}} p(t^1, t^2 | \phi, \psi) p(\phi, \psi | A_{\pi'}) d\phi d\psi$. When π' is not refinement of π , we need to know the dimension of $A_\pi \cap A_{\pi'}$. Consider a map $f : b \rightarrow v$, which maps the block b to a vector $v \in \{0, 1\}^K$, the i th component of v is $1_{\{i \in b\}}$. And denote $\dim(S)$ be the dimension of space S . A_π can be equivalently defined as $A_\pi = \{(\phi, \psi) : M_\pi * (\phi - \psi) = 0\}$, M_π is a matrix with rows be $v_b = f(b)$, $\forall b \in \pi$, that is to say (ϕ, ψ) are in the null space of linear transformation M_π . We have following lemma

Proof of lemma 1

Proof. Let V denote the orthogonal space of $\phi - \psi$, when $(\phi, \psi) \in A_{\pi_1} \cap A_{\pi_2}$, and $\dim(A_{\pi_1} \cap A_{\pi_2}) = \dim(\phi - \psi) + \dim(\psi) = 2K - \dim(V) - 1$. Also let $\pi_1 = \{b_1^1, \dots, b_s^1\}$, $\pi_2 = \{b_1^2, \dots, b_t^2\}$. The corresponding vectors are v_1^1, \dots, v_s^1 and v_1^2, \dots, v_t^2 . We claim there must be a $b_i^1 \in \pi$ whose corresponding v_i^1 is linear independent with v_1^2, \dots, v_t^2 . If not, for every v_i^1 there exists $\alpha_1^i, \dots, \alpha_t^i$ such that

$$v_i^1 = \sum_{j=1}^t \alpha_j^i v_j^2 \quad (*)$$

If $b_j^2 \cap b_i^1 \neq \emptyset$, then multiply v_j^2 on both sides of (*), we obtain $v_i^1 * v_j^2 = \alpha_j^i (v_j^2)^2$, as v_j^2 are orthogonal vectors, and $v_i^1 * v_j^2 > 0$ implies $\alpha_j^i > 0$. Consider $x = f(b_j^2 \setminus b_i^1)$, we have $x * v_i^1 = 0$ and we multiply x on both sides of (*) to obtain $\alpha_j^i v_j^2 * x = 0$, thus x must be zero vector and $b_j^2 \setminus b_i^1 = \emptyset$, which implies $b_j^2 \subset b_i^1$. That is to say when $b_j^2 \cap b_i^1 \neq \emptyset$, b_j^2 must be subset of b_i^1 . So b_i^1 is union of some blocks in π_2 . Which implies π_2 is refinement of π_1 ,

contradiction.

Consequently there exists $b \in \pi_1$ with $v(b)$ linear independent with $v(b'), b' \in \pi_2$. $\dim(V)$ is at least $N(\pi_2) + 1$, $\dim(A_{\pi_1} \cap A_{\pi_2}) < \dim(A_{\pi_2})$ \square

Proof of theorem 3 and theorem 4

Proof. Given the condition that $\alpha_k = 1, \forall k$ and $\beta_b = \sum_{k \in b} \alpha_k$, recall $p(A_\pi | t^1, t^2) = \sum_{\pi' \in \text{RF}(\pi)} J(t^1, t^2, \pi')$ and $J(t^1, t^2, \pi) = \frac{1}{c'} \prod_{b \in \pi} \frac{\Gamma(\beta_b + t_b^1 + t_b^2)}{\Gamma(\beta_b + t_b^1) \Gamma(\beta_b + t_b^2)}$. Assuming there are K subgroups, since n_1 and n_2 goes to infinite at same rate, for simplicity we assume $n = \sum_{i=1}^K t_i^1 = \sum_{i=1}^K t_i^2$, $t^1 \sim \text{multinomial}(\phi)$, $t^2 \sim \text{multinomial}(\psi)$ and $t_b^1 = \sum_{i \in b} z_i^1$ and $t_b^2 = \sum_{i \in b} z_i^2$, so $t_b^1 \sim \text{binomial}(n, \Phi_b)$ and $t_b^2 \sim \text{binomial}(n, \Psi_b)$, where $\Phi_b = \sum_{i \in b} \phi_i$ and $\Psi_b = \sum_{i \in b} \psi_i$. Let $f(n, b) = \frac{\Gamma(\beta_b + t_b^1 + t_b^2)}{\Gamma(\beta_b + t_b^1) \Gamma(\beta_b + t_b^2)}$, then

$$J(z^1, z^2, \pi) \propto \prod_{b \in \pi} f(n, b)$$

$\log f(n, b) = \log(\Gamma(\beta_b + t_b^1 + t_b^2)) - \log(\Gamma(\beta_b + t_b^1)) - \log(\Gamma(\beta_b + t_b^2))$, notice that t_b^1, t_b^2 and β_b are integers, and when x is integer, $\Gamma(x)$ is the factorial of $(x-1)$. We have $\log f(n, b) = \log((\beta_b + t_b^1 + t_b^2 - 1)!) - \log((\beta_b + t_b^1 - 1)!) - \log((\beta_b + t_b^2 - 1)!) = \log((\beta_b + t_b^1 + t_b^2 - 1)!) - \log((\beta_b + t_b^1 - 1)!) - \log((\beta_b + t_b^2 - 1)!) \approx (\beta_b + t_b^1 + t_b^2 - 1) \log(\beta_b + t_b^1 + t_b^2 - 1) - (\beta_b + t_b^1 - 1) \log(\beta_b + t_b^1 - 1) - (\beta_b + t_b^2 - 1) \log(\beta_b + t_b^2 - 1) + O(\log(n))$.

Plug into $f(n, b)$ we have:

$$\log f(n, b) \approx (\beta_b + t_b^1 - 1) \log(1 + \frac{t_b^2}{\beta_b + t_b^1 - 1}) + (\beta_b + t_b^2 - 1) \log(1 + \frac{t_b^1}{\beta_b + t_b^2 - 1}) + O(\log(n))$$

as $\beta_b \log(\beta_b + t_b^1 + t_b^2 - 1) \sim O(\log(n))$ and by law of large number and slusky's theorem, $\log(1 + \frac{t_b^2}{\beta_b + t_b^1 - 1}) \rightarrow \log(1 + \frac{\Psi_b}{\Phi_b})$, $\log(1 + \frac{t_b^1}{\beta_b + t_b^2 - 1}) \rightarrow \log(1 + \frac{\Phi_b}{\Psi_b})$ a.s. and $\frac{\log f(n, b)}{n} \rightarrow \Phi_b \log(1 + \frac{\Psi_b}{\Phi_b}) + \Psi_b \log(1 + \frac{\Phi_b}{\Psi_b})$ a.s. We have:

$$\frac{\log(\prod_{b \in \pi} f(n, b))}{n} \rightarrow \sum_b [\Phi_b \log(1 + \frac{\Psi_b}{\Phi_b}) + \Psi_b \log(1 + \frac{\Phi_b}{\Psi_b})] \quad a.s.$$

To find the maxima (Φ, Ψ) , we fix Ψ and let $C = \frac{\log(\prod_{b \in \pi} f(n, b))}{n} + \lambda(\sum_{b \in \pi} \Phi_b - 1)$, we have

$\frac{\partial C}{\partial \Phi_b} = \log(1 + \frac{\Psi_b}{\Phi_b}) + \lambda$, stationary point is $\Phi_b = \Psi_b, \forall b$. and for the hessian matrix $\frac{\partial^2 C}{\partial \Phi_b^2} = -\frac{\Psi_b}{\Phi_b^2 + \Phi_b \Psi_b} < 0$ and $\frac{\partial^2 C}{\partial \Phi_b \partial \Phi_{b'}} = 0$, if $b \neq b'$, that is to say the hessian matrix is a diagonal matrix with every diagonal elements to be negative, so it is negative definite, and our objective function is concave. The maxima is the stationary point $\Phi = \Psi$. And when $\Phi = \Psi$, $\frac{\log(\prod_{b \in \pi} f(n, b))}{n} = 2 \ln(2)$ a constant not dependent on partition π and Φ . That is to

say if $(\phi, \psi) \in A_{\pi_1} \cap A_{\pi_2}$ and $(\phi, \psi) \notin A_{\pi_3}$. Then we would have $\lim_{n \rightarrow \infty} \frac{\log(\prod_{b \in \pi_1} f(n, b))}{n} = \lim_{n \rightarrow \infty} \frac{\log(\prod_{b \in \pi_2} f(n, b))}{n}$ and $\lim_{n \rightarrow \infty} [\frac{\log(\prod_{b \in \pi_1} f(n, b))}{n} - \frac{\log(\prod_{b \in \pi_3} f(n, b))}{n}] = c > 0$, which implies:

$$(A) \quad \frac{J(t^1, t^2, \pi_3)}{J(t^1, t^2, \pi_1)} \rightarrow 0 \quad a.s.$$

To investigate the limit of $\frac{J(t^1, t^2, \pi_1)}{J(t^1, t^2, \pi_2)}$, We use inequalities that $\sqrt{2\pi}n^{n+\frac{1}{2}}e^{-n} \leq n! \leq en^{n+\frac{1}{2}}e^{-n}$ holds for all nonnegative integers n . Plug in $f(n, b)$, we have:

$$(1) \quad \beta_b + \log\sqrt{2\pi} - 3 + g(n, b) \leq f(n, b) \leq \beta_b - 2\log\sqrt{2\pi} + g(n, b)$$

$$g(n, b) = (\beta_b + t_b^1 - \frac{1}{2})\log(1 + \frac{t_b^2}{\beta_b + t_b^1 - 1}) + (\beta_b + t_b^2 - \frac{1}{2})\log(1 + \frac{t_b^1}{\beta_b + t_b^2 - 1}) - (\beta_b - \frac{1}{2})\log(\beta_b + t_b^1 + t_b^2 - 1)$$

Based on inequalities (1), $\sum_{b \in \pi} f(n, b)$ only differ with $\sum_{b \in \pi} g(n, b)$ by a constant. By Taylor's expansion $\log(1 + x) = \log 2 + \frac{1}{2}(x - 1) + O((x - 1)^2)$, we have $\log(1 + \frac{t_b^2}{\beta_b + t_b^1 - 1}) = \log 2 + \frac{1}{2}(\frac{t_b^1 - t_b^2 + 1 - \beta_b}{\beta_b + t_b^1 - 1}) + O_p((\frac{t_b^1 - t_b^2 + 1 - \beta_b}{\beta_b + t_b^1 - 1})^2)$ and under condition $\Phi_b = \Psi_b$, $\frac{(t_b^1 - t_b^2 + 1 - \beta_b)^2}{\beta_b + t_b^1 - 1}$ is $O_p(1)$. Plug in $g(n, b)$

$$g(n, b) = \log 2 * t_b^1 + \log 2 * t_b^2 - (\beta_b - \frac{1}{2})\log(\beta_b + t_b^1 + t_b^2 - 1) + O_p(1)$$

and sum up

$$(2) \quad \sum_{b \in \pi} g(n, b) = 2n\log 2 - \sum_{b \in \pi} (\beta_b - \frac{1}{2})\log(\beta_b + t_b^1 + t_b^2 - 1) + O_p(1)$$

Notice that when two partition π_1, π_2 have same number of blocks b and $\Phi_b = \Psi_b, \forall b \in \pi_1 \cup \pi_2$,

$$\begin{aligned} \sum_{b \in \pi_1} g(n, b) - \sum_{b' \in \pi_2} g(n, b') &= \sum_{b' \in \pi_2} (\beta_{b'} - \frac{1}{2})\log(\beta_{b'} + t_{b'}^1 + t_{b'}^2 - 1) - \sum_{b \in \pi_1} (\beta_b - \frac{1}{2})\log(\beta_b + t_b^1 + t_b^2 - 1) + O_p(1) \\ &= \sum_{b' \in \pi_2} (\beta_{b'} - \frac{1}{2})\log(\frac{\beta_{b'} + t_{b'}^1 + t_{b'}^2 - 1}{n}) - \sum_{b \in \pi_1} (\beta_b - \frac{1}{2})\log(\frac{\beta_b + t_b^1 + t_b^2 - 1}{n}) \\ &\quad + \sum_{b' \in \pi_2 - \frac{1}{2}} (\beta_{b'} - \frac{1}{2})\log(n) - \sum_{b \in \pi_1 - \frac{1}{2}} (\beta_b - \frac{1}{2})\log(n) + O_p(1) \\ &= O_p(1) + \sum_{b \in \pi_1} \frac{1}{2}\log(n) - \sum_{b' \in \pi_2} \frac{1}{2}\log(n) \\ &= O_p(1) \end{aligned}$$

When π_1 and π_2 have same number of blocks,

$$(B) \quad \frac{J(t^1, t^2, \pi_1)}{J(t^1, t^2, \pi_2)} \rightarrow O_p(1) \quad a.s.$$

When π_1 have less blocks than π_2 , $\sum_{b' \in \pi_2} g(n, b') - \sum_{b \in \pi_1} g(n, b) = O_p(\log(n))$

$$(C) \quad \frac{J(t^1, t^2, \pi_1)}{J(t^1, t^2, \pi_2)} \rightarrow 0 \quad a.s.$$
